Is 2d Turbulence a Conformal Turbulence?

Gregory Falkovich[*] and Amihay Hanany

February 1, 2008

Abstract

A critical analysis of the conformal approach to the theory of 2d turbulence is delivered. It is shown, in particular, that conformal minimal models cannot give a general turbulent solution, which should provide for constant fluxes of all vorticity integrals of motion.

The problem of small-scale spectrum of two-dimensional turbulence is a peculiar problem among the variety of turbulent systems. The point is that dimensional considerations do not give a steady spectrum that corresponds to the vorticity cascade. The spectrum obtained from dimensional analysis is $E(k) \propto k^{-3}$ [1] which yields a logarithmic infrared divergence after substitution into the equations for the correlation functions. Kraichnan's attempt to save the spectrum from nonlocality by introducing the slow factor $\ln^{-1/3} k$ attains convergence only in the first order of perturbation theory [2] while the next orders reveal divergences with higher powers of the logarithm: $\ln^2$ etc. The fact that the powers of the logarithm increase with the order of perturbation theory suggests that a substantial renormalization of the index occurs. No successful attempts to work out the divergences or to show that they are cancelled are known to us. The existence of alternative predictions for the steady spectrum $E(k) \propto k^{-4}$ by Saffman [3] and $E(k) \propto k^{-11/3}$ by Moffatt [4], show that this is still an open problem.

A fairly new approach to the problem has recently been introduced by Polyakov [5]. He suggested to borrow a set of correlation functions from conformal field theory to satisfy a chain of equations following from Euler's equation. Conformal invariance is assumed for the set of the simultaneous correlation functions (not for the Euler equation itself). This is based on

the idea that nonlinear interaction renormalizes all the properties in such a way that at criticality (for an infinite Reynolds number, in our case) system possesses the highest possible symmetry (absent in the initial equation). It is convenient to start from the Navier-Stokes equation written for the vorticity field $\omega(\mathbf{x}, t)$

$$\dot{\omega} + e_{\alpha\beta}\partial_\alpha\psi\partial_\beta\Delta\psi = \nu\Delta\omega , \quad (1)$$

ψ is a stream function giving the velocity field as $v_\alpha = e_{\alpha\beta}\partial_\beta\psi$. Here and below we use the notation $\partial/\partial x_\alpha = \partial_\alpha$.

Our aim is to find a stationary set of equal time correlation functions $I_n(\mathbf{x}_1, \dots, \mathbf{x}_n) = \langle \omega(\mathbf{x}_1, t) \dots \omega(\mathbf{x}_n, t) \rangle$. The brackets denote an average with some time independent probability distribution:

$$\sum_{p=1}^n \langle \omega(\mathbf{x}_1, t) \dots \dot{\omega}(\mathbf{x}_p, t) \dots \omega(\mathbf{x}_n, t) \rangle = 0 .$$

Such a stationary set is expected to exist in the inertial interval of scales, i.e., for distances that are much less than the scale L of an external pump and much larger than the viscous scale a . It is possible, then, to neglect viscosity in (1) using instead a careful point splitting procedure [5] for the nonlinear term

$$e_{\alpha\beta}\partial_\alpha\psi(\mathbf{x})\partial_\beta\Delta\psi(\mathbf{x}) = \lim_{a \rightarrow 0} e_{\alpha\beta}\partial_\alpha\psi(\mathbf{x} + \mathbf{a})\partial_\beta\Delta\psi(\mathbf{x} - \mathbf{a})$$

where “lim” implies angle averaging. To calculate different-point pair correlators like $\psi(\mathbf{x} + \mathbf{a})\psi(\mathbf{x} - \mathbf{a})$, the fusion rule of the type

$$[\psi][\psi] = [\phi] + \dots \quad (2)$$

should be used. Here we follow the notations of Ref.5 so that $[\psi]$ means the conformal class of ψ , i.e. itself together with the operators $L_{-n_1} \dots L_{-n_k}\psi$, L_{-n} being Virasoro generators [6]. Both ψ and ϕ are presumed to be taken from a set (primary fields) of some conformal field theory.

Polyakov suggested to use the so called minimal models [6] which contain a finite number of primary fields. The main subject of this paper is to show that a minimal model cannot serve as a general turbulent solution.

The primary field ϕ provides the main contribution in the operator product expansion (OPE) (2) in the small-scale region, i.e. it has the smallest conformal dimension. The important thing is that the scaling indices (dimensions) of the fields are not additive so generally $\Delta_\phi \neq 2\Delta_\psi$ and a dimension

defect appears. The energy density in the wave number space is expressed via $|\psi|^2$ and is

$$E(k) \propto k^{4\Delta_\psi+1} , \quad (3)$$

To choose an appropriate solution from the wealth of conformal solutions, one should impose some additional conditions that follow from the symmetries or conservation laws specific for the problem in question. According to Fjortoft's theorem (see e.g. [7]), the vorticity is the relevant quantity in the problem of small-scale turbulence (while the energy flux determines large-scale turbulence). Following Kraichnan [1] who developed a simple and efficient (though uncontrollable, of course) closure in terms of double correlation functions, the enstrophy

$$H_2 = \int \omega^2(\mathbf{x}) d^2x ,$$

which is a motion integral of Euler's equation is usually taken into account. A steady turbulence spectrum in the small-scale region should provide for a constant enstrophy flux over the scales which yields [5]

$$\langle \dot{\omega}(x+r)\omega(x) \rangle \propto r^0 = \text{const} . \quad (4)$$

Putting $\omega = \Delta\psi$ and $\dot{\omega} \propto (L_{-2}\bar{L}_{-1}^2 - \bar{L}_{-2}L_{-1}^2)\phi$, Polyakov obtained [5]

$$(\Delta_\phi + 2) + (\Delta_\psi + 1) = 0 . \quad (5)$$

As one can see, the enstrophy flux is expressed through the triple correlation function which can be expressed by the fusion rule (2) in terms of the double correlation function.

Equation (5) can be obtained also by requiring the rate of the enstrophy dissipation to remain constant while the viscosity ν goes to zero:

$$\frac{dH_2}{dt} = \nu \int^{1/a} k^2 H_k dk \propto \nu a^{-6-4\Delta_\psi} \propto \nu^{\frac{3+\Delta_\phi+\Delta_\psi}{\Delta_\phi-\Delta_\psi}} . \quad (6)$$

The last estimate was given by using the expression for the viscous scale $\nu \propto a^{2\Delta_\psi-2\Delta_\phi}$ that follows from the comparison of the nonlinear and the viscous terms in the Navier-Stokes equation. The natural physical assumption that the main dissipation stems from small scales is valid if $\Delta_\psi > -3/2$ or $\Delta_\psi > \Delta_\phi$ as it can be seen from (5,6).

Note that Kraichnan's dimensional approach would correspond to additive dimensions $\Delta_\phi = 2\Delta_\psi$ giving thus $\Delta_\psi = -1$ and $E(k) \propto k^{-3}$. However, we have arguments that suggest that this is not a conformal solution from the set of minimal models (see Appendix).

To ensure that the conformal set of correlators is a steady solution, Polyakov imposed an extra condition requiring that rhs of (2) (which determines the time derivatives of the correlators) vanishes in the ultraviolet limit. Since $\psi(z_1)\psi(z_2) = (z_1 - z_2)^{\Delta_\phi - 2\Delta_\psi}\phi(z_2) + \dots$ as $z_1 \rightarrow z_2$, the following inequality arises:

$$\Delta_\phi > 2\Delta_\psi, \quad (7)$$

thus, using (5), $\Delta_\psi < -1$.

Conditions (5) and (7) by no means determine a single solution. The minimal model (2,21) presented by Polyakov [5] is nothing but the first example from an infinite family. The curious reader can find the first few hundred solutions in our preprint [10]. Polyakov's solution corresponds to the minimal number of primary fields (in this case 10). One could, in particular, find the minimal model (5,72) that gives $\Delta_\psi = \Delta_{(1,25)} = -7/6$ and $E(k) \propto k^{-11/3}$ as in Moffatt's spectrum.

Usually, when speaking about a turbulent solution carrying a constant flux, one should check that two conditions are satisfied: i) The solution should be local in k -space which means that distant scales do not interact substantially; this should be provided by the convergence of the integral determining the flux in k -space; ii) The constant that arise in this (converging) integral should be nonzero and have the correct sign to satisfy the boundary conditions in k -space, i.e., the pumping and damping. Any solution of (5) and (7) violates both of these conditions.

Inequality (7) means that $\Delta_\psi < -1$ i.e. the spectrum (3) is steeper than Kraichnan's one (which yields an infrared logarithmic divergence) so that a power infrared divergence arises for any solution. To show this, let us consider the Euler equation in the momentum representation:

$$\frac{\partial \omega_k}{\partial t} = \int \Gamma_{12} \omega_1^* \omega_2^* \delta(\mathbf{k} + \mathbf{k}_1 + \mathbf{k}_2) d^2 k_1 d^2 k_2.$$

Here the vertex $\Gamma_{12} = [\mathbf{k}_1 \mathbf{k}_2](k_1^{-2} - k_2^{-2})$. The equation for the enstrophy density $h_2(\mathbf{k}, t)\delta(\mathbf{k} + \mathbf{k}') = \langle \omega_k \omega_{k'} \rangle$ by virtue of the conservation law can be written as a continuity equation $\dot{h}_2 + \text{div } \mathbf{P}_2 = 0$. The flux is constant in a

steady state:

$$P_2 = 2\pi \int_0^k k dk \int \Gamma_{12} \langle \omega_k \omega_1 \omega_2 \rangle \delta(\mathbf{k} + \mathbf{k}_1 + \mathbf{k}_2) d^2 k_1 d^2 k_2. \quad (8)$$

This is the Fourier transform of (4). Infrared convergence of (8) is determined by the asymptotics of the triple correlation function at $k_1 \ll k \simeq k_2$. Such an asymptotics is expressed via the second-order correlation function [8]:

$$\langle \omega_k \omega_1 \omega_2 \rangle = J_{k12} h_2(k_1) \Phi(k) (k_1/k) \delta(\mathbf{k} + \mathbf{k}_1 + \mathbf{k}_2). \quad (9)$$

Here $\Phi(k)$ is a power function which value is irrelevant to the problem of infrared convergence. Substituting (9) into (8), one gets the following integral

$$\int_{1/L} k h_2(k) dk. \quad (10)$$

If $h_2(k) \propto k^{-y_2}$, then (10) converges for $y_2 < 2$. It means that the energy spectrum $E(k)$ is local if it is less steeper than Kraichnan's k^{-3} . For the conformal solutions, $y_2 = -2\Delta_\psi$ and the convergence condition gives $\Delta_\psi > -1$. Equation (8) gives the scaling exponent of the triple correlation function $y_3 = 4$ which corresponds to (5) only in the case of convergence.

As far as the second condition (of nonzero flux) is concerned, the three-point function $\langle \psi \psi \psi \rangle \sim \langle \phi \psi \rangle$ is equal to zero since primary fields with different dimensions ($\Delta_\psi \neq \Delta_\phi$) are orthogonal for minimal models. The cases where ψ appears in the operator product expansion of $[\psi][\psi]$ (like those with $\Delta_\psi = \Delta_\phi = -3/2$ which one can find in [10]) break parity and therefore should be excluded. One can consider models with $\Delta_\psi = \Delta_\phi = -3/2$ but $[\psi][\psi]$ does not contain ψ in the OPE, this solution corresponds to the spectrum $E(k) \propto k^{-5}$ which seems to be unphysical since the dissipation integral (6) is not defined by the ultraviolet region but stems from the whole k -space implying thus the absence of the inertial interval in this case.

The conformal solutions in question are thus fluxless. This is quite natural since they are invariant under time reflection while a nonzero flux corresponds to an irreversible dissipation. The second difficulty (zero flux) remedies to some extent the first difficulty (nonlocality) since one should not require the convergence of the integrals that are identically zero. Physically this corresponds to the fact that the spectrum of a system in thermodynamic

equilibrium should not be local, unlike the cascade spectrum. A fluxless spectrum corresponds to an equilibrium case.

But, since we are discussing a nonequilibrium situation, there still remains the question, how the spectrum carries nonzero flux from the pumping region to the viscous region of scales. Polyakov's suggestion is that small (nonconformal) deviations from the power law due to infrared cut-off (pumping scale) could provide nonzero values for the enstrophy flux. (It is unclear if such a nonlocal yet cascade solution exists until it is explicitly found by solving the matching problem). The physical correlators are thus assumed to be close to the equilibrium ones in the inertial interval of scales. This is similar to what happens in two-dimensional optical turbulence described by the Non-linear Schrödinger Equation $i\Psi_t + \Delta\Psi + T|\Psi|^2 = 0$. For wave turbulence, the small-scale spectrum is $\epsilon(k) \propto k^{\alpha-m-d}$, where d is the space dimension and α and m are the scaling indices of the Hamiltonian coefficients (i.e. the frequency and the four-wave interaction coefficient respectively) [11]. For the NSE, $\alpha = d = 2$ and $m = 0$ so that the turbulent spectrum is $\epsilon(k) = \text{const}$ which coincides with the equilibrium equipartition. This spectrum (which is an exact steady solution) is fluxless too. Numerical simulations of the NSE show the nonequilibrium spectrum to be close to $\epsilon \approx \text{const}$ [12]. The same coincidence of the equilibrium and turbulent spectra takes place for common turbulence of Langmuir and ion sound waves in plasma, the spectra carrying fluxes acquire logarithmic factors in this case [11].

In our opinion, unlike the above cases of wave turbulence, conformal approach, namely, the assumption that the turbulent spectrum of 2d hydrodynamics should be close to an equilibrium one, is not based on solid ground. One would like to see the degeneracy that prescribes the coincidence of the turbulence spectrum with an equilibrium one.

Polyakov suggested to distort the spectra by analytical (in $\mathbf{x}$ -space) contributions. It corresponds to introducing $\delta(k)$ -terms in the momentum representation [13]. As a result, the flux (8) is determined by δ -terms and it is thus automatically independent of k . To get the condition (5), Polyakov required that the flux is independent of the infrared cut off which is the pump scale. This condition is satisfied in the (purely theoretical) case of the excitation by an external force independent of the velocity field. If one considers, however, a more physical case of a large-scale instability ($\partial h_2/\partial t + \text{div } P_2 = \gamma(k)h_2$), then the flux depends on the value of $h_2(k_0)$ at the pump region. If one estimates this value by extending the power solution from the inertial interval

$h_2(k) = P^a k^{-s}$, one has [14]

$$P \propto k_0^{(1-s)/(1-a)} .$$

What is important here is the factor $1 - s$. It has clear physical meaning: if one considers the integral of the total enstrophy $H = \int h_2(k) dk$, then $1 - s$ determines whether the enstrophy-containing region is in small or large scales. The enstrophy flux increases if one shifts or extends the pump toward the enstrophy-containing scale. Conformal solutions correspond to $s > 1$. There are thus three possibilities: 1) conformal solution cannot be matched with an instability increment; 2) the value $h(k_0)$ is much less than one naively estimated by extending the conformal spectrum; 3) $h(k_0)$ is well matched with a conformal part but into a pump integral you should substitute a much smaller value. Maybe 3) means that actually only small number of eddies grow due to the instability since most of large eddies are quasisteady and do not provide an instability leading to the direct cascade, while the whole set of eddies constitutes the conformal solution.

And what is more important, the above conformal approach does not account for the presence of an infinite set of motion integrals

$$H_n = \int \omega^n(\mathbf{x}) d^2x . \quad (11)$$

The conservation of H_n follows directly from the fact that the equation

$$\dot{\omega} + e_{\alpha\beta} \partial_\alpha \frac{\delta \mathcal{H}}{\delta \omega} \partial_\beta \omega = 0$$

conserves the integral $\int F(\omega) dx dy$, where F is an arbitrary function and the Hamiltonian $\mathcal{H}$ is an arbitrary functional of ω [not only $\mathcal{H} = \int \psi \omega dx dy$, which gives the lhs of (1)]. As one can see, even an infinite number of motion integrals does not fix the system but only its class.

Most authors feign indifference to the existence of the infinite number of motion integrals in 2d turbulence. Some arguments that only quadratic integrals (i.e. energy and squared vorticity) should be taken into account while considering thermodynamic equilibrium were given by Kraichnan [1, 15]. However, an arbitrary turbulent pump generally produces a nonzero input of all integrals H_n . The theory should describe the fate of these integrals.

One could try to presume that H_2 cascades while other integrals jump from the pumping to the damping and do not influence the structure of the

steady spectrum in the inertial interval of scales. Let us show that this is impossible and that the conditions for interaction locality are the same for any n .

The asymptotics of high-order correlation functions can be expressed via $h_2(k)$ by the same means as asymptotics (9). This can be done by using Wyld's diagram technique which allows one to express any correlation function via series containing the double correlation function and Green's function. For $k \rightarrow 0$, the double correlation function increases as k^{-x-y_2} while Green's function behaves as k^{-x} . Here x is a dynamic exponent, its value is irrelevant for our consideration. Since we are dealing with the case $y_2 > 0$ the relevant terms in the series are those which contain the double correlation function of small wavenumbers [8]. Such subsequences could be summed up to get exact expression for the asymptotics of any correlation function. Proceeding in this way we get the same convergence condition $y_2 > 2$ for any n . In particular, Kraichnan's spectrum gives the expression for P_n containing $(\ln kL)^{n-1}$. We should thus conclude that different vorticity integrals behave in the same way in k -space.

The conservation of H_n means that the Euler equation can be also represented in the form $\partial h_n(k)/\partial t + \text{div } P_n = 0$ so that the steady-state condition takes the form $P_n = \text{const}$. Here the spectral density h_n is expressed via the n -th correlator while the flux P_n via the $n+1$ -th correlator. Condition of the flux constancy gives the exponent of the n -th correlator $y_n = 2n - 2$ under the same condition of interaction locality as (8). Note that Kraichnan's spectrum formally satisfies these conditions (formally but not really because of the divergences). Indeed, the dimensions are additive in this case so that estimating the rate of the viscous dissipation of H_n ($n \geq 2$) similarly to (6), one gets

$$\dot{H}_n = \nu \int k^2 h_n(k) dk \propto \nu^{1/a} k^{\frac{(n-1)(\Delta_\psi+1)+\Delta_\phi+2}{\Delta_\phi-\Delta_\psi}}. \quad (12)$$

Kraichnan's spectrum gives $2\Delta_\psi = \Delta_\phi = -2$ so that (12) is satisfied for any n . Indeed, this corresponds to $\psi(r) \propto |r|^2$ so that the vorticity ω has zero scaling dimension (maybe logarithmic). All powers of the vorticity can thus have constant fluxes in k -space simultaneously. Actually, Kraichnan's spectrum would equally respect all conservation laws if it was local.

Note that we estimated the n -th correlation function in (12) in the simplest way just to show that $\Delta_\psi = -1$ formally satisfies all conservation laws.

As it is shown in the Appendix, a minimal model cannot have $\Delta_\phi = 2\Delta_\psi = -2$. Any conformal model that satisfies Polyakov's conditions (5,7) gives some negative defect of dimensions while calculating correlation functions. It means that the exponent in (12) is an upper bound so that by virtue of (5) one can get the inequality

$$\dot{H}_n < C\nu^{(n-2)(\Delta_\psi+1)/(\Delta_\phi-\Delta_\psi)}$$

with some positive constant C . Therefore, for Polyakov's solution with $\Delta_\psi < -1$, the integrals H_n with $n > 2$ are not dissipated in the inviscid limit. Consider, for example, the flux of H_3 : $\langle \dot{\omega}\omega^2 \rangle$. It is expressed via the correlator $\langle \phi\psi\psi \rangle$. If we fuse ϕ and ψ and take the most relevant operator, say, χ so that the condition of the flux constancy is $\Delta_\chi + 3 + \Delta_\psi + 1 = 0$. For example, for Polyakov's solution (2,21), $\Delta_\chi = -15/7$ so that the condition of the flux constancy is not satisfied and $dH_3/dt \rightarrow 0$ as $\nu \rightarrow 0$.

For the general case we need to calculate $\langle \dot{\omega}\omega^{n-1} \rangle$ which is given by $\langle \phi\psi^{n-1} \rangle$. If we take ψ^{n-1} to be the most relevant operator, say χ_{n-1} , in the OPE of $\underbrace{[\psi] \dots [\psi]}_{n-1}$ then we get the condition for constant flux of H_n :

$\Delta_\phi + 2 + (n-1) + \Delta_{n-1} = 0$, where Δ_n is the conformal dimension of χ_n . One can see that to satisfy these conditions for all n one needs infinite number of primary fields with negative dimension.

It was first pointed out in our preprint [10] that a minimal model cannot describe the spectrum with all vorticity fluxes. This was then recognized by Polyakov [13] who suggested that H_n can flow upscales for $n > 2$ and down-scales for $n = 2$. This seems unlikely. A general matching problem actually includes two integrals of motion: energy $\int v^2 dr$ and arbitrary functional of vorticity $\int F(\omega) dr$. The conservation of the latter follows from Kelvin's theorem on conservation of circulation. The integrals H_n are the Taylor coefficients of $F(\omega)$. It is natural to think that energy conservation determines large-scale while Kelvin's theorem determines small-scale turbulence. How one could divide Kelvin's theorem into two parts? Higher vorticity integrals cannot cascade upscales since their fluxes are incompatible with the inverse energy flux according to Fjortoft's theorem. Indeed, to absorb a small value of a large-scale vorticity one should simultaneously absorb a large value of the velocity (that is of the energy). Finite energy flux into the small scales means zero vorticity flux there.

Another possibility suggested in [13] is to break the symmetry assuming nonzero mean values of some fields. For fields with negative dimensions this strongly modifies the correlation functions [16]. In particular, the condition $P_n = \text{const}$ acquires the form $\Delta_\phi + 2 + (n-1 + \Delta_{n-1}) - \Delta_{n+1} = 0$. This condition gives $\Delta_n \approx n^2/4$ at $n \gg 1$ which is incompatible with the assumption on negative dimensions.

Let us summarize. We have the set of conformal models which are at best some particular solutions under an exotic condition of excitation. Kraichnan's spectrum formally respects all conservation laws but it is not a solution. How the true solution should look like? There are two important points: the infrared divergences and the presence of an infinite number of integrals of motion. Unlike naive expectation, a true spectrum should drop with k faster than Kraichnan's one to compensate a nonlocal gain of the integrals by the modes in the inertial interval directly from the pump (cf. with [17]). Power divergence that formally arises can be considered in a spirit of a field theory approach [18] and be included in the flux value as well as ultraviolet divergences in the theory of phase transitions are included in the true value of the transition temperature. It means that we should find a small-scale turbulent spectrum under the condition of the fixed value at pump scale. This value just determines the flux. Nonlocality is thus inevitable in any consistent approach to small-scale 2d turbulence. Indeed, it is easy to show that local vorticity cascade is impossible: if cascade was local, one can show that the exponent of n -th correlator would be $y_n = 2n - 2$ which immediately gives a logarithmic divergence. The positiveness of the anomalous dimensions (which are the differences between true y_n and $2n-2$) follows also from the inequality (see, e.g. [19]) $|v(l) - v(0)| \leq cl \ln l$ providing the absence of singularities in 2d velocity field. Large vortices play an important role in the direct vorticity cascade (see [7] and references therein).

Kraichnan's spectrum together with higher correlation functions having the exponents $y_n = 2n - 2$ seems to be a good bare solution which should be subjected to the procedure of an ultraviolet renormalization. Renormalization to be done should give the anomalous dimensions linearly depending on the order of the correlation function to provide for constant fluxes of all vorticity integrals [18].

A

Here we summarize all the conditions set by Polyakov on the solutions of a turbulence problem. We describe the algorithm we used in [10] to compute these solutions and give arguments why we think $\Delta_\psi = -1$ is not a minimal model solution.

The conditions are:

1. $\Delta_\psi + \Delta_\phi = -3$
2. $\Delta_\psi < -1$
3. ϕ must be the operator with the smallest dimension in the OPE of $[\psi]$ and $[\psi]$.

The minimal models are characterized by two positive co-prime integers (p, q) . For each minimal model (p, q) there is a set of $\frac{(p-1)(q-1)}{2}$ primary fields parameterized by two integers (n, m) , $1 \leq n \leq p-1$, $1 \leq m \leq q-1$. The spectrum of conformal dimensions is given by

$$\Delta_{(n,m)} = \frac{(nq - mp)^2 - (q - p)^2}{4pq}. \quad (13)$$

From this formula we see that $\Delta_{(n,m)} = \Delta_{(p-n, q-m)}$ and they both correspond to the same primary field. The scaling dimension of the primary field (n, m) is $2\Delta_{(n,m)}$. From the first condition, using (13), we get $\frac{p}{q}$ in terms of $n_\psi, m_\psi, n_\phi, m_\phi$

$$\frac{p}{q} = \frac{n_\psi m_\psi + n_\phi m_\phi - 8 + k}{m_\psi^2 + m_\phi^2 - 2},$$

where k is an integer defined by

$$k^2 = (n_\psi m_\psi + n_\phi m_\phi - 8)^2 - (n_\psi^2 + n_\phi^2 - 2)(m_\psi^2 + m_\phi^2 - 2). \quad (14)$$

This defines both p and q since they are co-prime. From the selection rules for the OPE we have n_ϕ, m_ϕ odd numbers and satisfy $1 \leq n_\phi \leq 2n_\psi - 1$, $1 \leq m_\phi \leq 2m_\psi - 1$. Requiring Δ_ϕ be minimal we get $(n_\phi q - m_\phi p) \approx 0$, this sets m_ϕ to be the nearest odd to

$$n_\phi \frac{n_\psi m_\psi - 8 \pm \sqrt{2m_\psi^2 - 16n_\psi m_\psi + 2m_\psi^2 + 60}}{n_\psi^2 - 2}. \quad (15)$$

An algorithm to calculate these turbulent solutions can be as follows. Given n_ψ, m_ψ , one can calculate m_ϕ from (15) and if k from (14) is an integer one can also find p and q . Using this algorithm we got a set of solutions up to $n_\psi = 10$ [10].

We also want to check if there exists a minimal model for which $\Delta_\psi = -1$ or $\Delta_\phi = -2$. We set $|n_\phi q - m_\phi p|$ to its minimal value and since p, q are co-prime there exist n_ϕ, m_ϕ such that $n_\phi q - m_\phi p = 1$ and we get, using (13), $-2 = \frac{1-(p-q)^2}{4pq}$ or

$$p^2 - 10pq + q^2 - 1 = 0. \quad (16)$$

for large p, q one can neglect 1 and solve the quadratic equation to get

$$\left(\frac{q}{p}\right)_\pm = 5 \pm \sqrt{24}, \quad (17)$$

the two solutions correspond to the symmetry between p and q . (This solution is irrational so in practice one can take p, q co-prime such that $\frac{p}{q}$ is close to this value, one can get any accuracy by taking large p, q). From $\Delta_\psi = -1$ and (17) we have m_ψ in terms of n_ψ as the nearest integer to

$$m_\psi = n_\psi \frac{q}{p} + 2\sqrt{\frac{q}{p}}. \quad (18)$$

The sequence defined by

$$a_{k+1} = 10a_k - a_{k-1} \quad a_0 = 0, \quad a_1 = 1$$

serves as a solution to (16) taking $p = a_k, q = a_{k+1}$ for any $k = 2, 3, \dots$, the k -th term is given by

$$a_k = \frac{(5 + \sqrt{24})^k - (5 - \sqrt{24})^k}{2\sqrt{24}}$$

Demanding that this (p, q) model has $\Delta_\psi = -1$ leads to the condition that $\sqrt{4pq+1}$ is an integer or, in terms of this sequence, that

$$\frac{(5 + \sqrt{24})^{2k-1} + (5 - \sqrt{24})^{2k-1} + 14}{24}$$

is an integer squared, which is unlikely.

In our preprint [10], one can find the models with (p, q) close to (17) and (n_ψ, m_ψ) satisfying (18): (13, 129), (39, 389), (109, 1082), (232, 2295) and (69, 686) with $-\Delta_\psi = \frac{561}{559}, \frac{391}{389}, \frac{59001}{58969}, \frac{17873}{17748}, \frac{7905}{7889}$ respectively.
